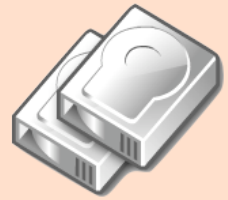
Chapter 10
Query Optimization
Exploring the Search Space of Alternative Query Plans

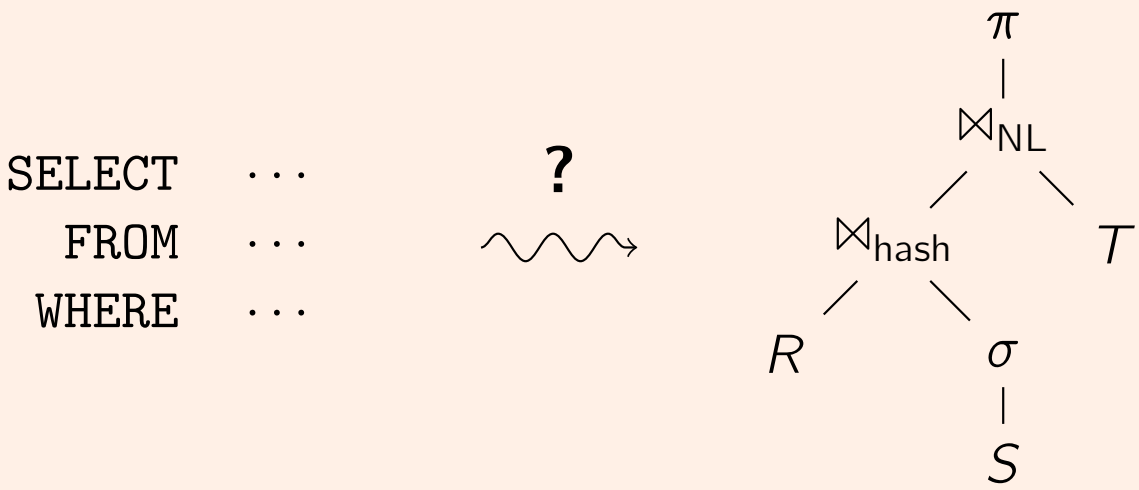
Architecture and Implementation of Database Systems
Summer 2016

Torsten Grust
Wilhelm-Schickard-Institut für Informatik
Universität Tübingen

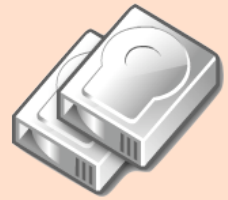


Finding the "Best" Query Plan

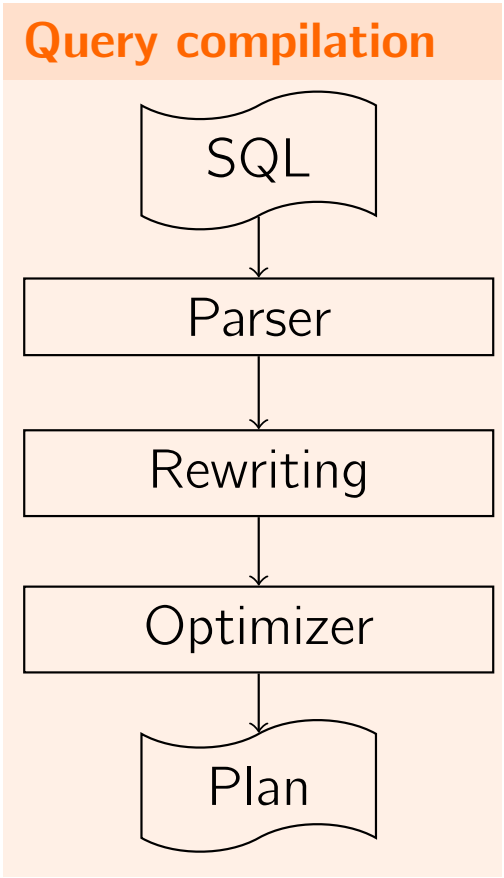
Throttle or break?



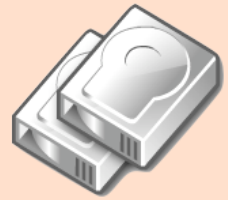
- We already saw that there may be more than one way to answer a given query.
  - Which one of the join operators should we pick? With which parameters (block size, buffer allocation, ...)?
- The task of **finding the best execution plan** is, in fact, the "holy grail" of any database implementation.



Plan Generation Process



- **Parser:** syntactical/semantical analysis
- **Rewriting: heuristic** optimizations independent of the current database state (table sizes, availability of indexes, etc.). For example:
  - Apply predicates early
  - Avoid unnecessary duplicate elimination
- **Optimizer:** optimizations that rely on a **cost model** and information about the current database state
- The resulting **plan** is then evaluated by the system's **execution engine**.

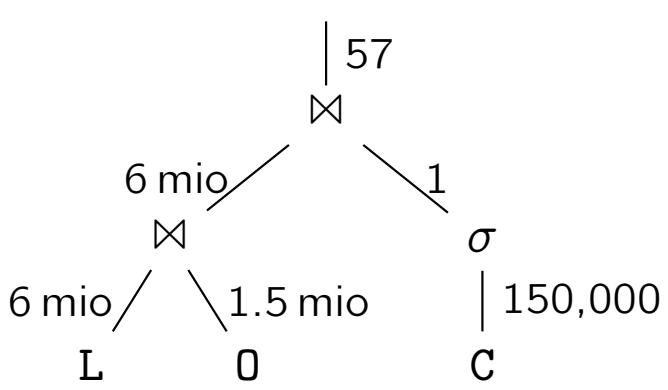


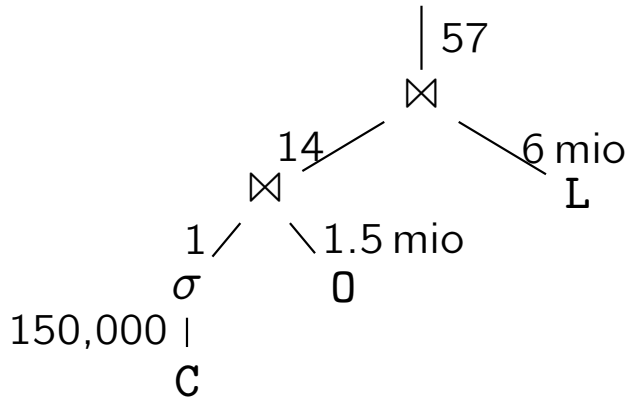
Impact on Performance

Finding the right plan can dramatically impact performance.

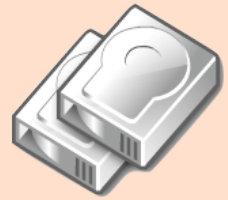
Sample query over TPC-H tables

```
1 SELECT L.L_PARTKEY, L.L_QUANTITY, L.L_EXTENDEDPRICE
2   FROM LINEITEM L, ORDERS O, CUSTOMER C
3  WHERE L.L_ORDERKEY = O.O_ORDERKEY
4    AND O.O_CUSTKEY = C.C_CUSTKEY
5    AND C.C_NAME = 'IBM Corp.'
```





- In terms of execution times, these differences can easily mean "seconds versus days."



The SQL Parser

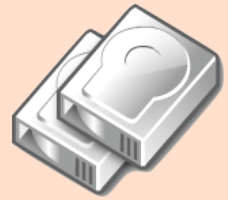
- Besides some analyses regarding the syntactical and semantical correctness of the input query, the parser creates an **internal representation** of the input query.
- This representation still resembles the original query:
  - Each `SELECT-FROM-WHERE` clause is translated into a **query block**.

Deriving a query block from a SQL SFW block

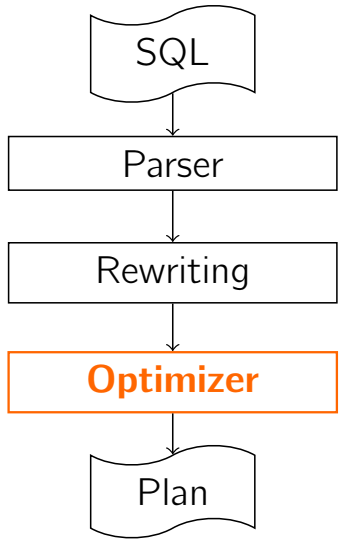
```
SELECT  proj-list
  FROM  R1, R2, ..., Rn
 WHERE  predicate-list
 GROUP BY  groupby-list
HAVING  having-list
```

$\rightarrow$

  - Each R_i can be a base relation or another query block.



Finding the "Best" Execution Plan



The parser output is fed into a **rewrite engine** which, again, yields a tree of query blocks.

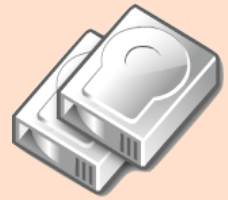
It is then the **optimizer's** task to come up with the optimal **execution plan** for the given query.

Essentially, the optimizer

1. **enumerates** all possible execution plans,
   (if this yields too many plans, at least enumerate the "promising" plan candidates)
2. determines the **quality** (cost) of each plan, then
3. **chooses** the best one as the final execution plan.

Before we can do so, we need to answer the question

- What is a "good" execution plan at all?



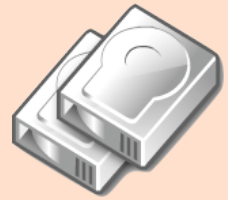
Cost Metrics

Database systems judge the quality of an execution plan based on a number of **cost factors**, *e.g.*,

- the number of **disk I/Os** required to evaluate the plan,
- the plan's **CPU cost**,
- the overall **response time** observable by the database client as well as the total **execution time**.

A cost-based optimizer tries to **anticipate** these costs and find the cheapest plan before actually running it.

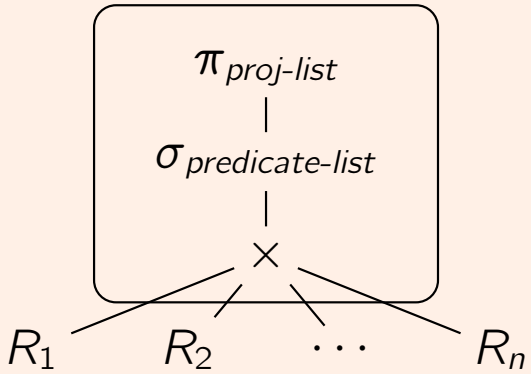
- All of the above factors depend on one critical piece of information: the **size of (intermediate) query results**.
- Database systems thus invest considerable effort into the derivation of **result size estimates**.



Result Size Estimation

Consider a query block corresponding to a simple SFW query Q.

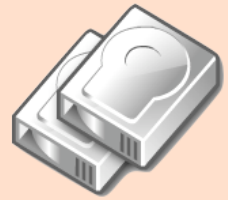
SFW query block



We can estimate the result size of Q based on

- the size of the input tables, $|R_1|, \ldots, |R_n|$, and
- the **selectivity** $sel(p)$ of the predicate *predicate-list*:

$$|Q| \approx |R_1| \cdot |R_2| \cdots |R_n| \cdot sel(\textit{predicate-list}) \quad .$$

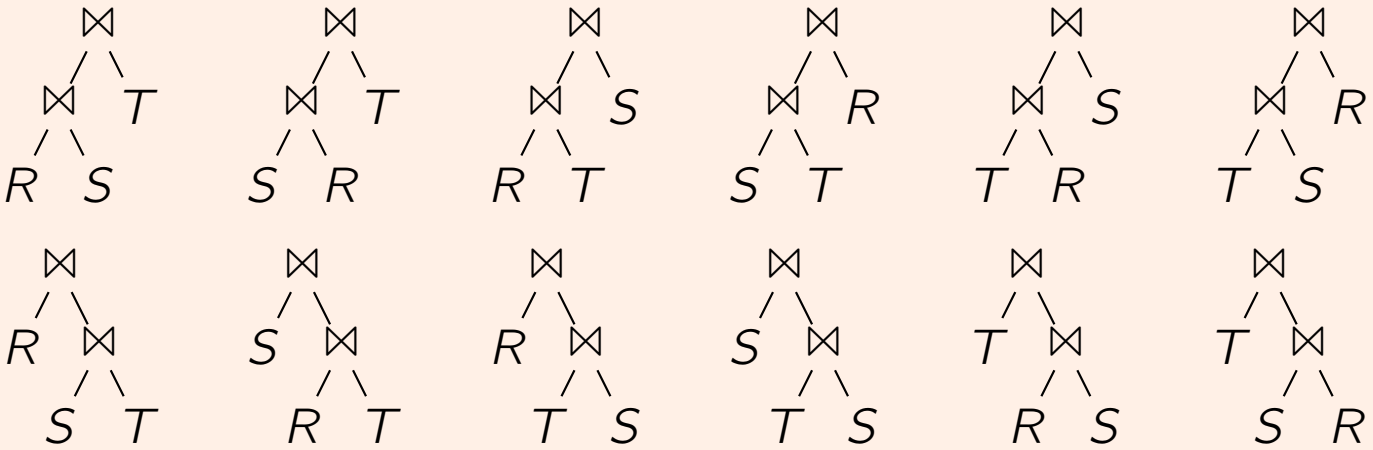


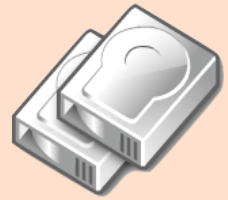
Join Optimization

- We've now translated the query into a graph of **query blocks**.
  - Query blocks essentially are a **multi-way** Cartesian product with a number of selection predicates on top.
- We can estimate the **cost** of a given **execution plan**.
  - Use result size estimates in combination with the cost for individual join algorithms discussed in previous chapters.

We are now ready to **enumerate** all possible execution plans, *i.e.*, all possible **2-way** join combinations for each query block.

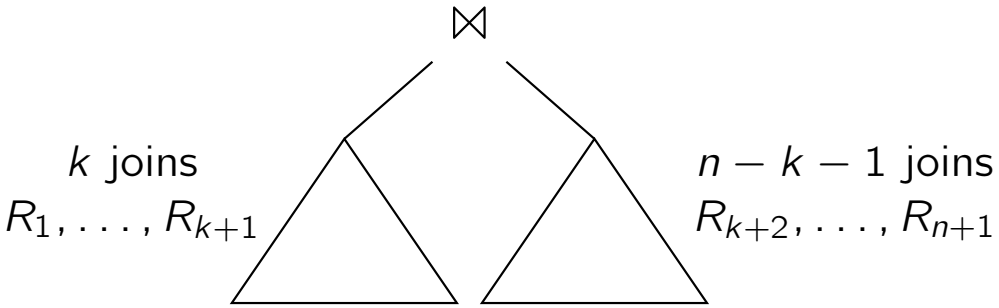
Ways of building a 3-way join from two 2-way joins





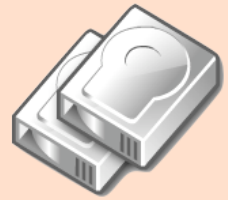
How Many Such Combinations Are There?

- A join over $n+1$ relations $R_1, \ldots, R_{n+1}$ requires n **binary joins**.
- Its **root-level operator** joins sub-plans of k and $n-k-1$ join operators ($0 \leqslant k \leqslant n-1$):



- Let C_i be the **number of possibilities** to construct a binary tree of i inner nodes (join operators):

$$C_n = \sum_{k=0}^{n-1} C_k \cdot C_{n-k-1} \quad .$$



Catalan Numbers

This recurrence relation is satisfied by **Catalan numbers**:

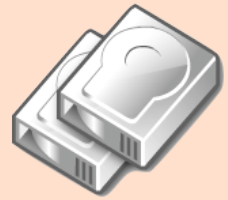
$$C_n = \sum_{k=0}^{n-1} C_k \cdot C_{n-k-1} = \frac{(2n)!}{(n+1)!n!} \quad ,$$

describing the number of ordered binary trees with $n+1$ leaves.

For **each** of these trees, we can **permute** the input relations (why?) $R_1, \ldots, R_{n+1}$, leading to:

Number of possible join trees for an $(n+1)$-way relational join

$$\frac{(2n)!}{(n+1)!n!} \cdot (n+1)! = \frac{(2n)!}{n!}$$



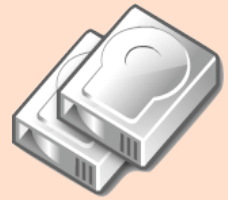
Search Space

The resulting search space is **enormous**:

Possible bushy join trees joining n relations

number of relations n	C_{n-1}	join trees
2	1	2
3	2	12
4	5	120
5	14	1,680
6	42	30,240
7	132	665,280
8	429	17,297,280
10	4,862	17,643,225,600

- And we haven't yet even considered the use of k **different join algorithms** (yielding another factor of $k^{(n-1)}$)!



Dynamic Programming

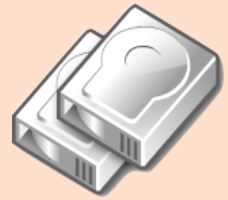
The traditional approach to master this search space is the use of **dynamic programming**.

Idea:

- Find the cheapest plan for an n-way join in n **passes**.
- In each pass k, find the best plans for all k-relation **sub-queries**.
- **Construct** the plans in pass k from best i-relation and $(k-i)$-relation sub-plans found in **earlier passes** $(1 \leqslant i < k)$.

Assumption:

- To find the optimal **global plan**, it is sufficient to only consider the optimal plans of its **sub-queries** ("Principle of optimality").



Dynamic Programming

Example (Four-way join of tables $R_{1,\ldots,4}$)

Pass 1 (best 1-relation plans)

Find the best **access path** to each of the R_i individually (considers index scans, full table scans).

Pass 2 (best 2-relation plans)

For each **pair** of tables R_i and R_j, determine the best order to join R_i and R_j (use $R_i \bowtie R_j$ or $R_j \bowtie R_i$?):

$$optPlan(\{R_i, R_j\}) \leftarrow \text{ best of } R_i \bowtie R_j \text{ and } R_j \bowtie R_i \ .$$

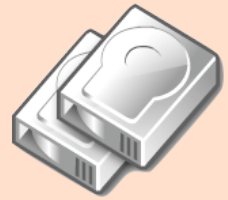
$\rightarrow$ 12 plans to consider.

Pass 3 (best 3-relation plans)

For each **triple** of tables R_i, R_j, and R_k, determine the best three-table join plan, using sub-plans obtained so far:

$$optPlan(\{R_i, R_j, R_k\}) \leftarrow \text{ best of } R_i \bowtie optPlan(\{R_j, R_k\}), \\ optPlan(\{R_j, R_k\}) \bowtie R_i, \quad R_j \bowtie optPlan(\{R_i, R_k\}), \ldots \ .$$

$\rightarrow$ 24 plans to consider.



Dynamic Programming

Example (Four-way join of tables $R_{1,\ldots,4}$ (cont'd))

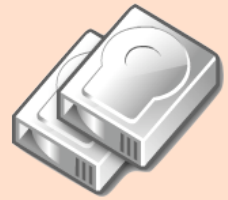
Pass 4 (best 4-relation plan)

For each set of **four** tables R_i, R_j, R_k, and R_l, determine the best four-table join plan, using sub-plans obtained so far:

$$\begin{aligned} optPlan(\{R_i, R_j, R_k, R_l\}) \leftarrow \text{ best of } & R_i \bowtie optPlan(\{R_j, R_k, R_l\}), \\ & optPlan(\{R_j, R_k, R_l\}) \bowtie R_i, \quad R_j \bowtie optPlan(\{R_i, R_k, R_l\}), \ldots, \\ & optPlan(\{R_i, R_j\}) \bowtie optPlan(\{R_k, R_l\}), \ldots \quad . \end{aligned}$$

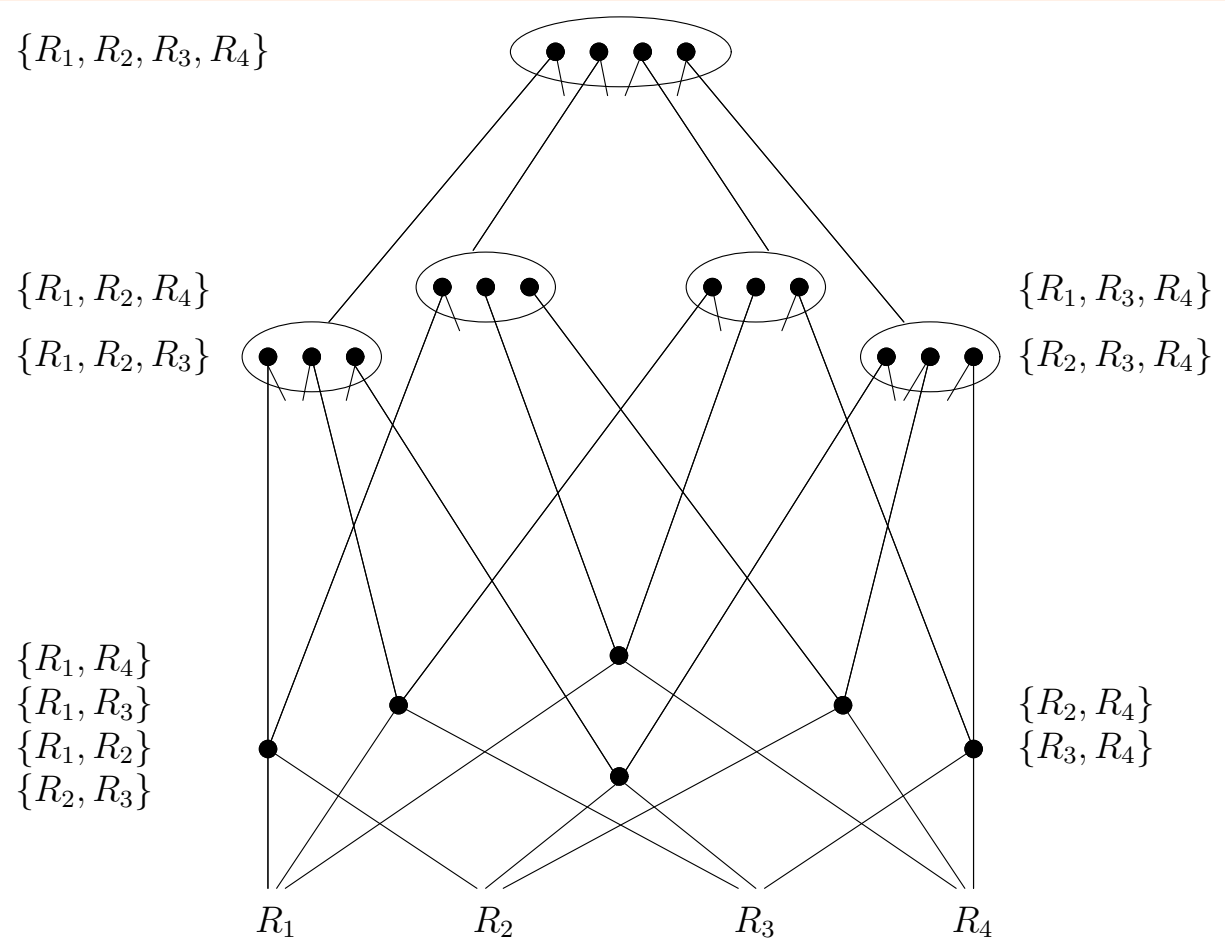
$\rightarrow$ 14 plans to consider.

- Overall, we looked at only **50** (sub-)plans (instead of the possible 120 four-way join plans; ↗ slide 12).
- All decisions required the evaluation of **simple** sub-plans only (**no need to re-evaluate** $optPlan(\cdot)$ for already known relation combinations $\Rightarrow$ use lookup table).

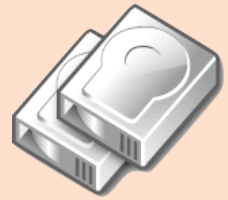


Sharing Under the Optimality Principle

Sharing optimal sub-plans



Drawing by Guido Moerkotte, U Mannheim



Dynamic Programming Algorithm

Find optimal n-way bushy join tree via dynamic programming

1 **Function:** `find_join_tree_dp` $(q(R_1, \ldots, R_n))$

2 **for** $i = 1$ **to** n **do**

3 $\quad optPlan(\{R_i\}) \leftarrow$ `access_plans` (R_i) ;

4 $\quad$ `prune_plans` $(optPlan(\{R_i\}))$;

5 **for** $i = 2$ **to** n **do**

6 $\quad$ **foreach** $S \subseteq \{R_1, \ldots, R_n\}$ **such that** $|S| = i$ **do**

7 $\quad\quad optPlan(S) \leftarrow \varnothing$;

8 $\quad\quad$ **foreach** $O \subset S$ with $O \neq \varnothing$ **do**

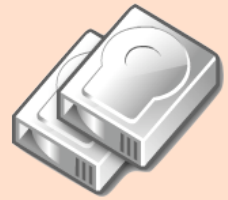
9 $\quad\quad\quad optPlan(S) \leftarrow optPlan(S) \cup$

10 $\quad\quad\quad\quad$ `possible_joins` $\left[\begin{array}{c} \bowtie \\ optPlan(O) \quad optPlan(S \setminus O) \end{array}\right]$;

11 $\quad\quad$ `prune_plans` $(optPlan(S))$;

12 **return** $optPlan(\{R_1, \ldots, R_n\})$;

- `possible_joins` $[R \bowtie S]$ enumerates the possible joins between R and S (nested loops join, merge join, etc.).
- `prune_plans` (set) discards all but the best plan from set.



Dynamic Programming—Discussion

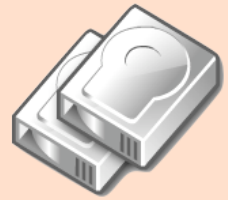
- Enumerate all non-empty true subsets of S (using C):

```
1    O = S & -S;
2    do {
3      /* perform operation on O */
4      O = S & (O - S);
5    } while (O != S);
```

- `find_join_tree_dp()` draws its advantage from **filtering** plan candidates early in the process.
  - In our example on slide 14, pruning in Pass 2 reduced the search space by a factor of 2, and another factor of 6 in Pass 3.
- Some **heuristics** can be used to prune even more plans:
  - Try to avoid **Cartesian products**.
  - Produce **left-deep plans** only (see next slides).
- Such heuristics can be used as a handle to balance plan quality and optimizer runtime.

DB2 Control optimizer investment

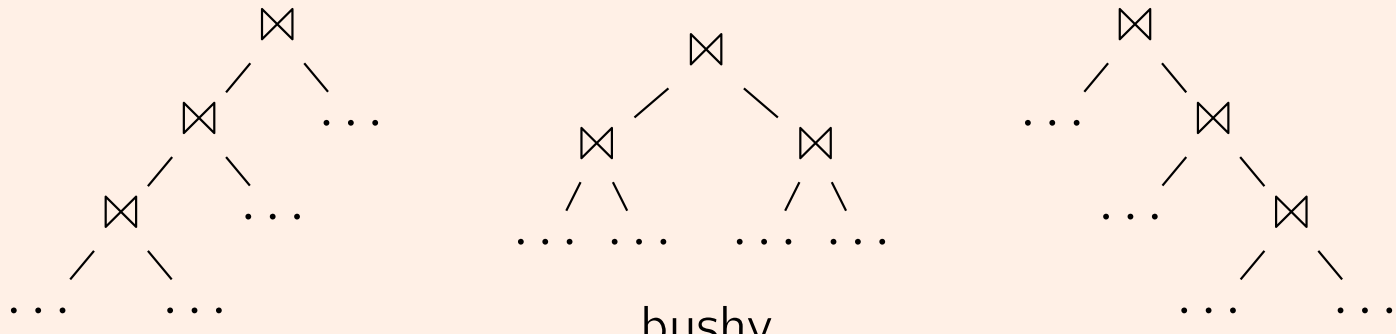
```
1    SET CURRENT QUERY OPTIMIZATION = n
```



Left/Right-Deep vs. Bushy Join Trees

The algorithm on slide 17 explores all possible shapes a join tree could take:

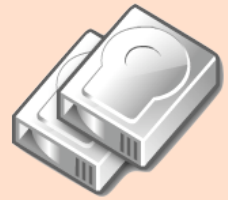
Join tree shapes



Actual systems often prefer **left-deep** join trees.[1]

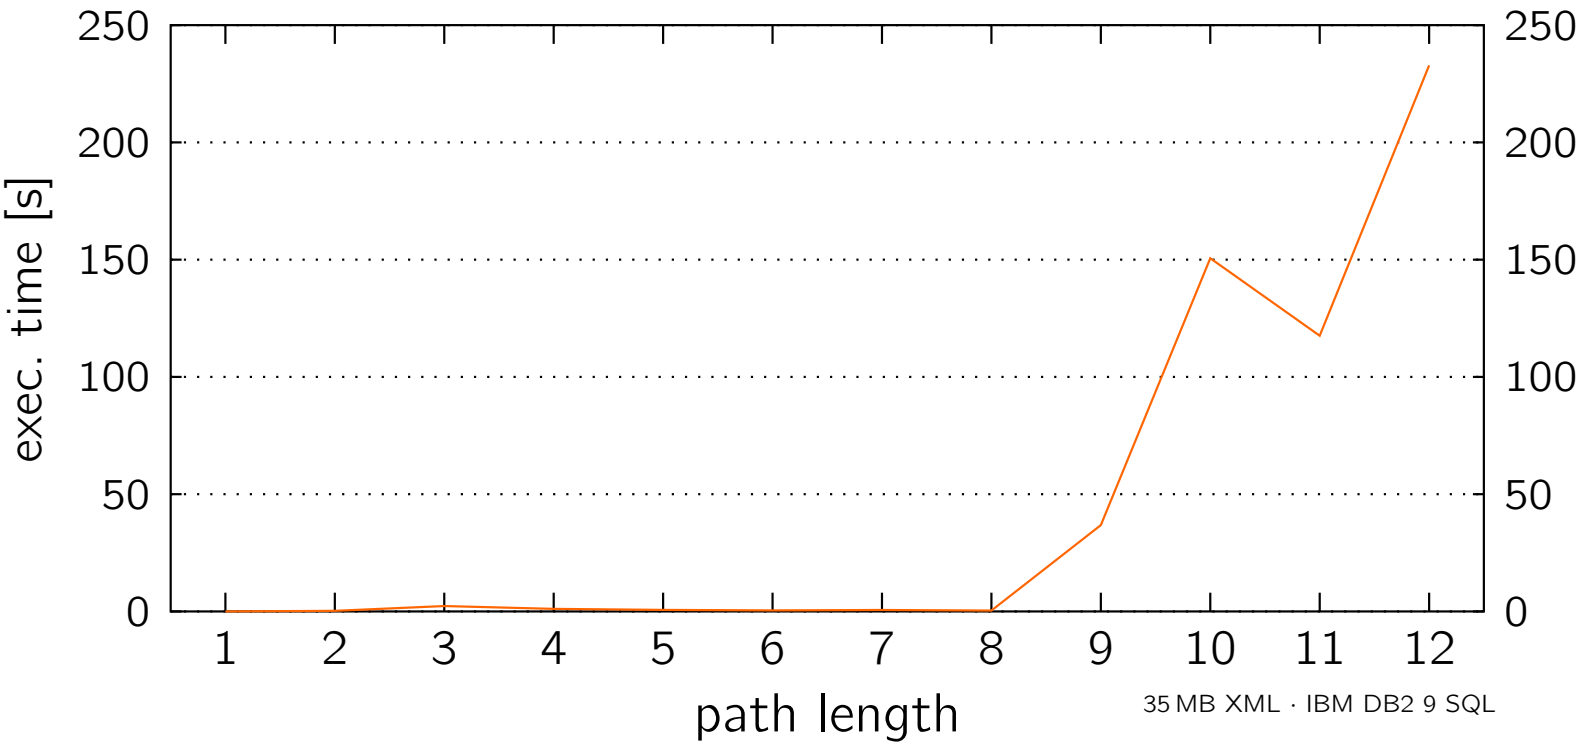
- The **inner** (rhs) relation always is a **base relation**.
- Allows the use of **index nested loops join**.
- Easier to implement in a **pipelined** fashion.

[1] The seminal **System R** prototype, *e.g.*, considered only left-deep plans.



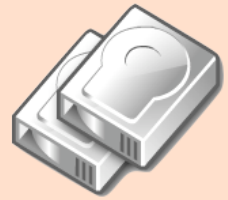
Join Order Makes a Difference

- XPath location step evaluation over relationally encoded XML data.[2]
- *n*-way self-join with a range predicate.



[2] ↗ Grust *et al.* Accelerating XPath Evaluation in Any RDBMS. *TODS 2004*.

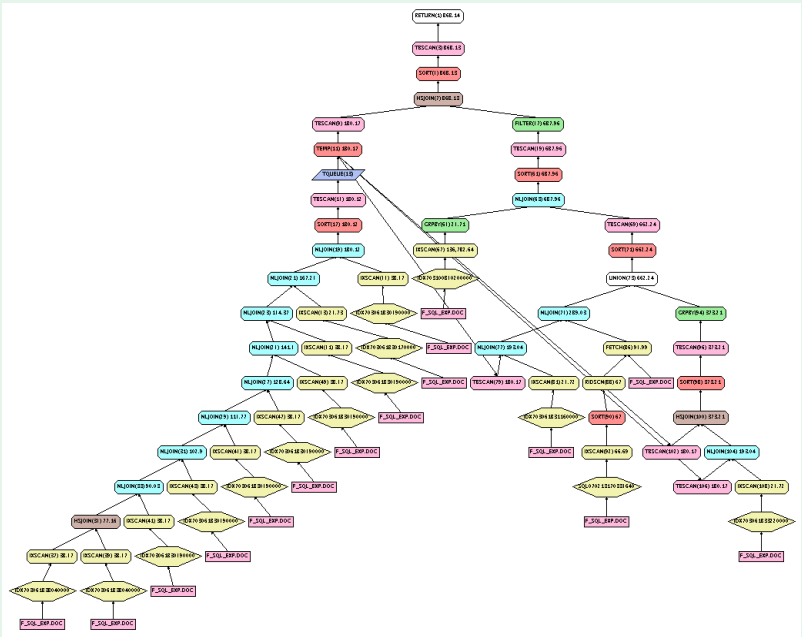
`http://www.pathfinder-xquery.org/`



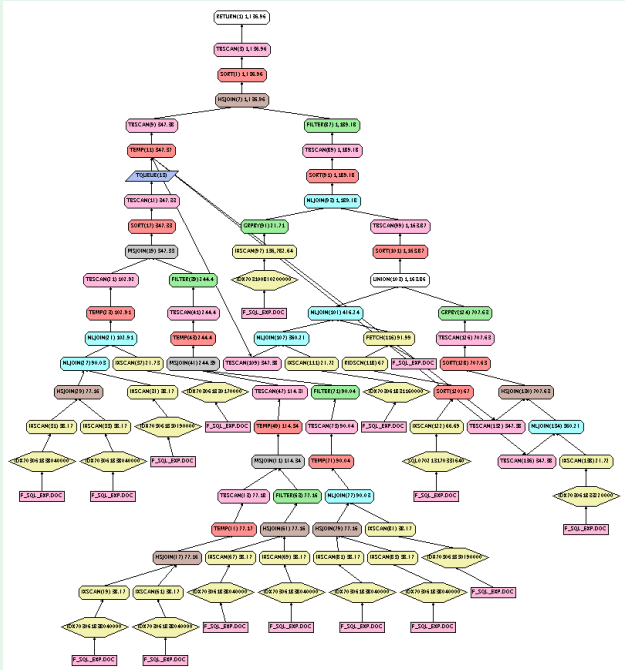
Join Order Makes a Difference

Contrast the execution plans for a path of 8 and 9 XPath location steps:

DB2 Join plans

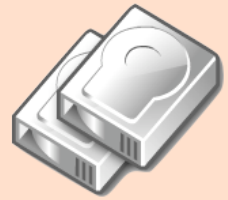


left-deep join tree



bushy join tree

⇒ DB2's optimizer essentially gave up in the face of 9+ joins.



Joining Many Relations

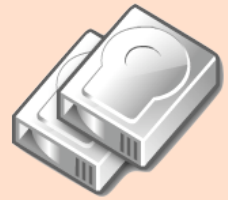
Dynamic programming still has **exponential** resource requirements:
(↗ K. Ono, G.M. Lohman, *Measuring the Complexity of Join Enumeration in Query Optimization*, VLDB 1990)

- time complexity: $\mathcal{O}(3^n)$
- space complexity: $\mathcal{O}(2^n)$

This may still be too expensive

- for joins involving many relations ($\sim$ 10–20 and more),
- for simple queries over well-indexed data (where the right plan choice should be easy to make).

The **greedy join enumeration** algorithm jumps into this gap.



Greedy Join Enumeration

Greedy join enumeration for n-way join

1 **Function:** `find_join_tree_greedy` $(q(R_1, \ldots, R_n))$

2 $worklist \leftarrow \varnothing$;

3 **for** $i = 1$ **to** n **do**

4 $\quad worklist \leftarrow worklist \cup$ `best_access_plan` (R_i) ;

5 **for** $i = n$ **downto** 2 **do**

$\quad$ // $worklist = \{P_1, \ldots, P_i\}$

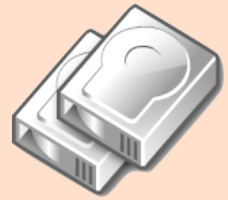
6 $\quad$ find $P_j, P_k \in worklist$ and $\bowtie_{\ldots}$ such that $cost(P_j \bowtie_{\ldots} P_k)$ is minimal ;

7 $\quad worklist \leftarrow worklist \setminus \{P_j, P_k\} \cup \{(P_j \bowtie_{\ldots} P_k)\}$;

// $worklist = \{P_1\}$

8 **return** single plan left in $worklist$;

- In each iteration, choose the **cheapest** join that can be made over the remaining sub-plans at that time (this is the "greedy" part).
- Observe that `find_join_tree_greedy ()` operates similar to finding the optimum binary tree for **Huffman coding**.



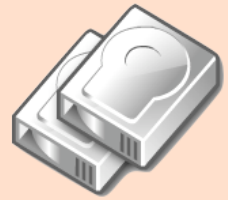
Join Enumeration—Discussion

Greedy join enumeration:

- The greedy algorithm has $\mathcal{O}(n^3)$ time complexity:
  - The loop has $\mathcal{O}(n)$ iterations.
  - Each iteration looks at all remaining pairs of plans in *worklist*. An $\mathcal{O}(n^2)$ task.

Other join enumeration techniques:

- **Randomized algorithms:** randomly rewrite the join tree one rewrite at a time; use **hill-climbing** or **simulated annealing** strategy to find optimal plan.
- **Genetic algorithms:** explore plan space by **combining** plans ("creating offspring") and **altering** some plans randomly ("mutations").



Physical Plan Properties

Consider the simple equi-join query

Join query over TPC-H tables

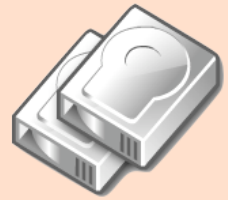
```
1 SELECT O.O_ORDERKEY
2   FROM ORDERS O, LINEITEM L
3  WHERE O.O_ORDERKEY = L.L_ORDERKEY
```

where table `ORDERS` is indexed with a **unclustered index** `OK_IDX` on column `O_ORDERKEY`.

Possible table access plans (1-relation plans) are:

`ORDERS`
- **full table scan**: estimated I/Os: $N_{\texttt{ORDERS}}$
- **index scan**: estimated I/Os: $N_{\texttt{OK\_IDX}} + N_{\texttt{ORDERS}}$.

`LINEITEM`
- **full table scan**: estimated I/Os: $N_{\texttt{LINEITEM}}$.



Physical Plan Properties

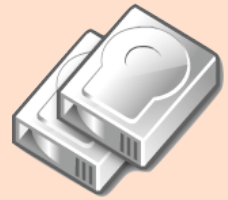
- Since the **full table scan** is the cheapest access method for both tables, our join algorithms will select them as the best 1-relation plans in Pass 1.[3]

  To **join** the two scan outputs, we now have the choices
  - **nested loops join**,
  - **hash join**, or
  - **sort** both inputs, then use **merge join**.

  Let us assume that sort-merge join is the preferable candidate, incurring a cost of $\approx 2 \cdot (N_{\texttt{ORDERS}} + N_{\texttt{LINEITEM}})$.

  $\Rightarrow$ **Overall cost:**
  $N_{\texttt{ORDERS}} + N_{\texttt{LINEITEM}} + 2 \cdot (N_{\texttt{ORDERS}} + N_{\texttt{LINEITEM}})$.

[3] Dynamic programming and the greedy algorithm happen to do the same in this example.



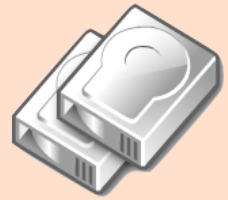
Physical Plan Properties—A Better Plan

It is easy to see, however, that there is a better way to evaluate the query:

1. Use an **index scan** to access `ORDERS`. This guarantees that the scan output is already **in** `O_ORDERKEY` **order**.
2. Then only **sort** `LINEITEM` and
3. join using **merge join**.

$\Rightarrow$ **Overall cost:** $\underbrace{(N_{\texttt{OK\_IDX}} + N_{\texttt{ORDERS}})}_{1} + \underbrace{2 \cdot N_{\texttt{LINEITEM}}}_{2\,/\,3}$.

Although more expensive as a standalone table access plan, the **use of the index (order enforcement) pays off later on** in the overall plan.

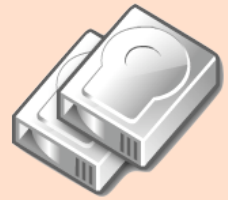


Physical Plan Properties: Interesting Orders

- The advantage of the index-based access to `ORDERS` is that it provides beneficial **physical properties**.
- Optimizers, therefore, keep track of such properties by **annotating** candidate plans.

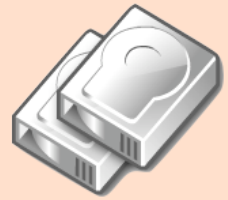
- System R introduced the concept of **interesting orders**, determined by
  - `ORDER BY` or `GROUP BY` clauses in the input query, or
  - join attributes of subsequent joins ($\rightsquigarrow$ merge join).

$\Rightarrow$ In `prune_plans()`, retain
  - the cheapest "unordered" plan **and**
  - the cheapest plan for each interesting order.



Query Rewriting

- Join optimization essentially takes a set of relations and a set of join predicates to find the best join order.
- By **rewriting** query graphs beforehand, we can improve the effectiveness of this procedure.
- The **query rewriter** applies **heuristic rules**, without looking into the actual database state (no information about cardinalities, indexes, etc.).
  In particular, the optimizer
  - **relocates predicates** (predicate pushdown),
  - **rewrites predicates**, and
  - **unnests queries**.



Predicate Simplification

Rewrite

Example (Query against TPC-H table)

```
1    SELECT *
2      FROM LINEITEM L
3     WHERE L.L_TAX * 100 < 5
```

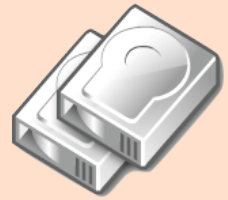
into

Example (Query after predicate simplification)

```
1    SELECT *
2      FROM LINEITEM L
3     WHERE L.L_TAX  < 0.05
```

✎ In which sense is the rewritten predicate simpler?

Why would a RDBMS query optimizer rewrite the selection predicate as shown above?



Introducing Additional Join Predicates

Implicit join predicates as in

Implicit join predicate through transitivity

```
1 SELECT *
2   FROM A, B, C
3  WHERE A.a = B.b AND B.b = C.c
```

can be turned into explicit ones:

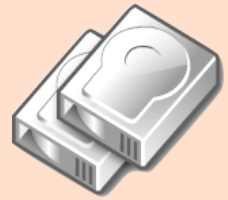
Explicit join predicate

```
1 SELECT *
2   FROM A, B, C
3  WHERE A.a = B.b AND B.b = C.c
4    AND A.a = C.c
```

This makes the following join tree feasible:

$$(\mathtt{A} \bowtie \mathtt{C}) \bowtie \mathtt{B} \quad .$$

(Note: $(\mathtt{A} \bowtie \mathtt{C})$ would have been a Cartesian product before.)



Nested Queries and Correlation

SQL provides a number of ways to write **nested queries**.

- **Uncorrelated** sub-query:

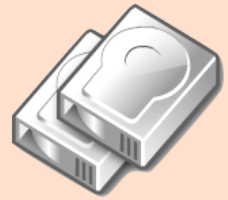
No free variables in subquery

```
1 SELECT *
2   FROM ORDERS O
3  WHERE O_CUSTKEY IN (SELECT C_CUSTKEY
4                        FROM CUSTOMER
5                       WHERE C_NAME = 'IBM Corp.')
```

- **Correlated** sub-query:

Row variable `O` occurs free in subquery

```
1 SELECT *
2   FROM ORDERS O
3  WHERE O.O_CUSTKEY IN
4              (SELECT C.C_CUSTKEY
5                 FROM CUSTOMER C
6                WHERE C.C_ACCTBAL < O.O_TOTALPRICE)
```



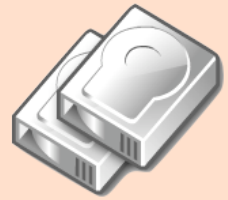
Query Unnesting

- Taking query nesting literally might be **expensive**.
  - An uncorrelated query, *e.g.*, need not be re-evaluated for every tuple in the outer query.
- Oftentimes, sub-queries are only used as a syntactical way to express a **join** (or a semi-join).
- The query rewriter tries to detect such situations and **make the join explicit**.
- This way, the sub-query can become part of the regular **join order optimization**.

✎ Turning correlation into joins

Reformulate the correlated query of slide 32 (use SQL syntax or relational algebra) to remove the correlation (and introduce a join).

↗ Won Kim. On Optimizing an SQL-like Nested Query. *ACM TODS*, vol. 7, no. 3, September 1982.



Summary

Query Parser

Translates input query into (SFW-like) **query blocks**.

Rewriter

Logical (database state-independent) optimizations; predicate simplification; query unnesting.

(Join) Optimization

Find "best" query execution plan based on a **cost model** (considering I/O cost, CPU cost, ...); data statistics (histograms); dynamic programming, greedy join enumeration; physical plan properties (interesting orders).

Database optimizers still are true pieces of art...
